Preliminary Exploration of Large-Scale Triangle Counting on Shared-Memory Multicore System

Jiyuan Zhang, Daniele G. Spampinato, Scott McMillan, Franz Franchetti

Abstract—As triangle counting is becoming a widely-used building block for a large amount of graph analytics applications, there is a growing need to make it run fast and scalable on large parallel systems. In this work we conduct a preliminary exploration on the optimizations of triangle counting algorithms on shared-memory system with large dataset.

I. INTRODUCTION

Graph analytics is becoming increasingly important in a growing number of domains and there is a need to build fast and scalable systems for graph analytics. Nowadays, there is a growing trend for the design of graph analytics engines for shared-memory systems [1]–[3]. Shared-memory system has lower communication costs and lower data access latency. This can potentially lead to better performance compared with distributed memory systems. On top of that, a state-of-art high-end multi-core machine can integrate hundreds of cores, and terabytes of memory [4]. This further enables shared memory systems to process large-scale datasets in memory.

In this work, we explore one of the basic applications in graph analytics: triangle counting. Triangle counting is one of the frequently computed building block operation in graph analytics, therefore it is important to make it run fast and scalable to large systems. There are rich amount of graph frameworks that can target a general set of graph applications. Those frameworks have different frontend designs [1]–[3], [5]–[7]. For example, [5] is based on vertex-iterator programming model where a utility function is supplied and executed on each vertex, [6] uses linear algebra language as primitives. And others are based on domain-specific languages, etc. However, those graph framework’s target are the broad set of graph applications, their backend optimizations may be too general to be effective for triangle countings.

In this work, we plan to study the optimizations specific for triangle counting on the shared-memory systems. There are different algorithms for triangle counting. And for these algorithms, one could have different implementations, including a variety of hashing and merging tweaks. In order to get optimal performance for triangle counting, it is essential to consider system characteristics, as well as input graph’s properties to find the effective optimization method. This paper conducts a preliminary explorations on whether such optimizations can be effective for large-scale triangle counting on shared-memory multi-core systems. The structure of the paper is as follows: the discussion of the triangle counting algorithm is presented in section II. Then the baseline parallel implementation is given in section III. Section IV discusses a variety of optimization techniques and analyzes whether they can be effective in practice. The performance results are presented in section V.

II. ALGORITHM

The straight-forward algorithm for triangle counting using the linear algebra language can be illustrated as [8], [9]:

\[ A^2 \circ A \]  

(1)

where A is the adjacency matrix of the input graph. The square of A gives all the wedges (connected two edges) and the element-wise multiplication with A closes the wedge and forms a triangle. Afterwards, the algorithm sums over each element in the resultant matrix. However, in this algorithm each triangle will be counted repetitively for six times. An improvement to reduce the double counting in the baseline algorithm can use half the adjacency matrix. In this way, each triangle will only be counted once.

There is an algorithm that can further reduce the triangle counting complexity. The compact-forward algorithm in [10] can outperform the above two baseline algorithms by greatly reducing the number of false positives. The algorithm consists of two steps. The first step is direction assignment: it assigns a direction to each undirected edge such that the edge points from the low-degree vertex to the high-degree vertex. Then the second step counts the number of triangles based on the directed graph. There are two benefits of introducing a direction to the edge: First of all, it can avoid double counting. Second, it reduces the (out-)degree of nodes, especially those with high degrees. As the counting has the quadratic complexity to the vertex’s (out-)degree and the high (out-)degree vertex dominates the computation among all the vertices, this can greatly reduce the complexity.

III. BASELINE PARALLEL TRIANGLE COUNTING

The most time consuming part of the compact forward algorithm is the second step—counting triangles from the directed graph. The pseudocode for this step is shown in Algorithm 1. In this step, the algorithm iterates every vertex
(v), and for each one of its (directed) neighbors u, sums up the number of common neighbors. We first run a baseline parallel triangle counting algorithm on the shared memory systems. The baseline implementation is based on [11]. The implementation simply parallelizes the loop among vertex v (line 3) and the subsequent loop among the neighborhood of v (line 4).

Algorithm 1 count triangles in directed graph

1: procedure TRI_COUNT(G) ▶ G is the directed graph
2:    count ← 0
3:    for v ∈ G.vertices do
4:        for u ∈ v.neighbors do
5:            count += common neighbors of u and v
6:        end for
7:    end for
8:    return count
9: end procedure

In terms of the counting phase in line 5, the implementation has explored two basic ways to implement counting — hashing-based method and sort-merge based method. The author finds the sort-merge based implementation is faster than the hash-based method.

IV. PRELIMINARY EXPLORATION ON OPTIMIZATIONS

Counting the common elements of two vertex’s neighbor list is the most time consuming computation. In this section, we will mostly focus on the optimizations for the counting phase in line 5. Counting the common elements of two neighbor lists is essentially finding out the intersecting elements between two sets. Therefore optimizations explored previously in set-intersection problems may be applied here.

Algorithm 2 count common elements in two sorted lists

1: procedure COUNT_COMMON(A, B) ▶ The A, B are two sorted lists
2:    i ← 0, j ← 0, counts ← 0
3:    while i < A.size AND j < B.size do
4:        if A[i] < B[j] then
5:            i++
6:        else if A[i] > B[j] then
7:            j++
8:        else
9:            i++, j++, count++
10:    end if
11:    end while
12:    return count
13: end procedure

a) Hashing: One technique to optimize the set intersection operation is to use hashing. The hashing method maps each vertex’s neighborhood into a corresponding hash table. To count the common elements in two vertex’s neighborhood, we can iterate through the elements in the smaller neighborhood list and probes into the hash table of the bigger neighborhood. The cost of the hashing based set intersection method is \( \min(n_1, n_2) \), where \( n_1 \) is the size of small list and \( n_2 \) is the size of the large list.

b) Merging: is another technique to count the common elements in two lists. It first sorts each vertex’s neighborhood list in increasing order and counts the common elements of two sorted lists by linear scan through them. The baseline code to count the intersection of two sorted lists via merging method is shown in Algorithm 2. The cost for the merging based set intersection is \( \max(n_1, n_2) \).

c) Exploiting binary search to accelerate merging: When the two list size is quite different, we can binary search the smaller list in the large one. The cost of the counting phase can be reduced to \( n_1 \log(n_2) \).

d) Exploiting SIMD to accelerate merging: There has been plenty of work exploring how to utilize the SIMD unit to accelerate set intersection computation [12]–[14]. We implemented a baseline SIMD algorithm based on [14]. Assume the system SIMD width is four-elements, the SIMD intersection algorithm is illustrated with an example in Figure 1. In this example, during the first iteration the first four-element of list A and B will be compared (the instructions used will be explained subsequently). Based on comparison of the tail elements (i.e. the 4th element), one of the pointers is decided to move. In the example case, pointer of the list B will advance to the next 4-element block because its 4th element is smaller than list A. In second iteration, the first four elements of A are compared with the second 4-element block of B and finally the second 4-element blocks of A and B are compared.

On CPUs with AVX instruction set architecture, the algorithm exemplified in Fig. 1 can be implemented using _mm_cmppeq and _mm_shuffle intrinsics. _mm_cmppeq can compare multiple elements at once and produce a resulting bit mask. In order to conduct all-to-all comparisons between A and B, only one _mm_cmppeq is not enough — the SIMD block of B needs to left-shift using _mm_shuffle intrinsics and then compare with A again till the right-most element in B’s element block is compared with the left-most element of A. The process is illustrated in Fig. 2.

Fig. 1: SIMD algorithm assuming simd width is 4 elements.
e) hybrid hashing and merging: A hybrid method represents a node’s neighborhood with a hybrid structure between sparse list and hash table. The hybrid method partitions the data range into fix-sized \((K)\) blocks. Each block is indexed by its base value and has an associated bit-vector of length \(K\). Each bit of the bit-vector indicates the existence of an element on that position. For example, given a list \(\{0, 1, 4, 52, 102, 493, 534\}\) and \(K = 64\), the list can be compressed as \(\{0, 64, 448, 512\}\). We can see the size of the list reduces from 8 to 4. In this way, the number of comparisons can be reduced subsequently. To count the common elements in the compressed block list, it firstly scan through the block lists to find blocks with common base values via the merge-sort methods and then count the common elements in the two blocks by comparing the two corresponding indicator vectors.

A. Profiling and Analysis

Whether the above algorithms will work largely depends on the property of the dataset. In this section, we start with the profiling results of some representative graphs datasets in order to exam the effectiveness of the above techniques.

Cit-Patents. This dataset has 3,774,768 vertices and 16,518,947 edges. The original maximum degree 793. The maximum degree after sorting is 73. The degree distribution is shown in Fig. 5. We can see that after direction assignment, the out-degree distribution still follows a power-law distribution. Majority of vertices has small out-degree.

Friendster. This dataset has 65,608,366 vertices and 1,806,067,135 edges. The original maximum degree among all the nodes is 5214. The maximum out-degree in the directed graph is 2389. And their distribution is in Fig. 6.

Graph500-scale23. This dataset has 4,606,314 vertices and 129,250,705 edges. The original maximum degree 272176. The maximum degree after sorting is 1376. The degree distribution is shown in Fig. 7.

We highlight the following observations based on the profilings:

Observation 1. In the directed graph, the number of nodes with high out-degrees is small. However, intersections between those high out-degree nodes’ neighbor list dominates the total run-time. And this is not difficult to verify. If we assume that after reordering the rows from highest degree to lowest degree in the adjacent matrix of the graph, the number of non-zero element(nnz, equivalently out-degree) follows a power-law distribution over the rows, then the comparing cost per row will also be skewed and resemble a power-law distribution. As plotted out in Figure 3, we can see that if the nnz element follows a power-law distribution of \(x^{-2}\), then in all the two list(a.k.a. rows) comparisons, the top 40% rows takes 50% of the total comparison cost. If the nnz element distribution is \(x^{-2}\), then the top 10% rows will take up over 50% of the total comparison cost. In general, more skewed the nnz element distribution is in the graph’s adjacent matrix, the more skewed the computation cost will be towards the dense part of the matrix. Figure 4 shows the real time and computation cost distribution on some given datasets. Consistent with the theoretical results, the computation cost is also mostly centered among the beginning rows with larger out-degrees.

Observation 2. The density of the high-degree nodes’ neighbor lists is still very sparse. Each node’s neighbor list is a sequence of numbers whose value lies in the range from 0 to \(N - 1\). We introduce the metric Density to measure the sparsity of a vertex’s neighborhood vector. Density is the number of elements divided by their maximum value. The smaller the density, the sparser the neighbor list is. Knowing the density is helpful to determine the hashing parameters as for a sparser neighborhood list, it may require a larger hash table. In the directed graph, usually the vertices with higher degree have higher density. For the scale23 graph, the highest density neighborhood is around 0.763. The top 10% high out-degree vertex has density between 0.1 – 0.7. For the friendster graph, the highest density 0.01. The top 10 percent high out-degree vertex has density between 0.001 – 0.01. We can see that as a graph scales, the density of the vertex’s neighbor can be sparser.

B. Understanding the optimizations

a) Hashing: Using hashing method, we didn’t see any improvement on the speed. Although the complexity of hashing method is \(min(n1, n2)\). However, this is most effective when there is at least an order of magnitude difference between \(nA\) and \(nB\) (i.e. \(max(n1, n1) \gg min(n1, n2)\)). But profiling shows that the comparison cases where \(max(n1, n2) > 10 * min(n1, n2)\) only makes up a small part in all the two-pair list comparisons, according to our observation 1. In other words, majority of time is spent to compare lists \(n1 \approx n2\) and both \(n1\) and \(n2\) are large. Therefore, hashing technique that is helpful to accelerate a dense list versus a sparse list is unable to observe performance improvement.

b) Exploiting binary search to accelerate merging: Similar to the hashing method, the binary search method does not accelerate the computation, because the binary search also requires the size of two sorted lists to be very different in order to have observable speedup.

c) Exploiting SIMD to accelerate merging: This method can be applied regardless of the relative size of the two lists. Therefore, it can be effective to accelerate the CountCommon process of two big lists. And we will show the results in the next section.

d) Hybrid hashing and merging: Whether the Hybrid hashing and merging can be effective highly depends on the density of the neighbor list: whether the list has elements condensed together that can be compressed. Otherwise the size reduction in the compressed block list is not sufficient.
Table IV shows the performance on the graph500-scale23 dataset. We studied the Friendster dataset and the result suggests the original neighbor list is not friendly for such compressing. As shown in Table I, the base list size after 256bit compression only reduces from 1,806,067,135 elements to 1,690,408,139 elements (about 7% reduction). Moreover, the comparison operation then becomes more expensive when there is a match in the base value. One needs very delicate design in order to draw benefits from such methods.

V. PERFORMANCE RESULTS

Hardware  The systems used in our experiments were supported by Pittsburgh Supercomputing Center [4], [15], [16]. The experiment was tested on three types of hardware settings:

- **Single Core**: A single core out of the small multicore system, used to study the scalar performance.
- **Small multi-core**: A small multicore system which has two Intel Haswell (E5-2695 v3) CPUs(sockets) and each CPU has 14 cores.
- **Large multi-core**: A large shared-memory multicore system from HPE Integrity Superdome X. It has 16 Intel Xeon E7-8880 v4 CPUs(sockets) with 22 cores per CPU socket, 55MB Last Level Cache.

**Results**  We present the performance results on the above three systems in Table II-IV.

- **Single Core**: Table II shows the speedup of our SIMD-based set intersection over a scalar implementation on a single core (Intel Haswell (E5-2695 v3)) using the small dataset. We can see that SIMD can bring about 1.2x to over 3x times speedups over scalar implementation.
- **Small multi-core**: Table III shows the SIMD speedup on the small multicore system with media-size dataset. Similar to single-core performance, the result shows that our SIMD implementation is about 1.4x to 3.6x speedup on this multicore system.
- **Large multi-core**: Table IV shows the performance on the large shared-memory multicore system with large dataset. Those large datasets are generated using the kronecker graph generator [17]. The kron35 dataset runs over 2-days and unfinished by the given submission time frame. We are unable to give the execution time. We estimate the time will be between 60 hours to 100 hours.

**Performance comparison with distributed system.** Last year graph challenge champion Pearce, et al. [18] presented their triangle processed per second per core they achieved is 1.9MTPS at highest (for WDC dataset, they counted 9.65T triangles in 808.7s on 256 node where each node has 24 cores). Their total number of cores is higher than ours. Therefore their overall execution time is shorter. When it comes to performance per-core. The triangle processed per second per core they achieved is 3.1MTPS. Our implementation can get 3.1MTPS per core.
